STORAGE OF MATERIALS

insert a)

This invention relates to the stabilisation and

5 storage of materials. The principal envisaged field of application is materials employed in the biochemical field and some pharmaceuticals.

A few biologically active materials (e.g. some proteins) are sufficiently stable that they can be isolated,

10 purified and then stored in solution at room temperature. For most materials however this is not possible and some, more elaborate form of stabilisation/storage procedure must be used.

As discussed in our co-pending European application

15 published as EP-A-383569 a number of storage techniques are known but are not universally applicable to materials which give rise to a storage problem.

That pending application discloses the storage of materials by incorporating them into a water-soluble or

20 water-swellable substance which is in an amorphous, glassy or (much less preferably) rubbery state.

That application discloses the preparation of storable compositions by preparing a solution of the substance(s) to be stored and a water-soluble or swellable substance, then

25 evaporating water from the solution at room temperature or with some heating. Temperatures of 37°C and 60°C are exemplified. The solutions were simply held in a stationary container during drying.

It is of course considered prudent to minimise the application of heat when drying a material which is not particularly stable. Freeze drying is a prime example of this.

5   Spray drying is a known process for drying a solution or suspension to a solid, particulate form. The process entails delivering the solution or suspension into a flow of preheated gas, usually air, whereupon water rapidly evaporates from the droplets. It is widely used in the

10   manufacture of detergent powders and in that field it is well known that certain materials are not stable to spray-drying conditions.

        Spray drying has been used to kill microbial cells, for instance in dairy products as disclosed by A. Chopin et al, Can J. Microbiol 23, 716 (1977). EP-A-366303 discloses the

15   use of spray drying to dry a cell composition with the intention that the cells will be killed but cell components such as enzymes will be recoverable from the dried composition. Spray drying has been used in attempts to dry

20   microbial cells to a state of suspended animation from which viable cells can be recovered, but even in a relatively favourable case losses of 97% were recorded after 30 days storage at room temperature as disclosed by I.A. Abd el Gawad et al Egyptian Journal of Dairy Science, 17 273

25   (1989).

        Surprisingly, we have now found that spray drying can be used to make storable compositions by drying mixtures of the material(s) to be stored and aqueous solutions of a

water-soluble or water-swellable substance which forms a glassy (or possibly rubbery) state on drying.

According to this invention, therefore, we provide a process of rendering a material suitable for storage

5 comprising spraying into a hot gas stream, an aqueous mixture of the material and a carrier substance which is water-soluble or water-swellable, thereby drying the mixture to particles in which the said carrier substance is in a glassy or rubbery state, and separating the particles from

10 the gas stream.

This process is of course also a process for preparing a storable composition.

The aqueous mixture of the material for storage and the carrier substance will generally be formed by mixing the

15 material with the carrier substance in the presence of water. However, it is possible that the material to be stored will be provided as a solution which already contains a substance which is able to form a glass and so is suitable as a carrier substance, so that deliberate addition of a

20 carrier substance is unnecessary.

As will be explained in more detail below it is preferred that the composition produced by the drying procedure displays a glass transition temperature of at least 20°C, preferably at least 30°C and possibly well above

25 this e.g. at least 50°C.

The invention may be utilised for stable storage of a single material, or for a mixture of materials which have little or no effect on each other.

However, a further possibility is that the invention is used to produce a composition which contains a plurality of materials which (when in contact with water) form part or all of a reacting system. These materials may be fairly simple chemicals.

Yet another possibility is that the material comprises viable biological cells.

Material Stored (i) inanimate materials

The material(s) stabilised for storage may potentially be any of a wide range of materials which are ordinarily liable to undergo chemical reaction, and so are not stable during storage at ambient temperature of 20°C.

One category of materials to which the invention is applicable is proteins and peptides, including derivatives thereof such as glycoproteins. Such proteins and peptides may be any of: enzymes, transport proteins, e.g. haemoglobin, immunoglobulins, hormones, blood clotting factors, other blood plasma components and pharmacologically active proteins or peptides.

Another category of materials to which the invention is applicable comprises nucleosides, nucleotides, dinucleotides, oligonucleotides (say containing up to four nucleotides) and also enzyme cofactors, whether or not these are nucleotides. Enzyme substrates in general are materials to which the invention may be applied.

The material for stabilisation and storage may be isolated from a natural source, animal, plant, fungal or

bacterial, may be produced by and isolated from cells grown by fermentation in artificial culture, or may be produced by chemical synthesis. Such cells may or may not be genetically transformed cells.

5   The material will need to be soluble in aqueous solution, at least to the extent of forming a dilute solution which can be used for incorporation into the carrier substance.

As mentioned above, a possibility is to store more

10 than one component of a reacting system in a glass. This can be useful for materials which will be required to be used together in, for example, an assay or a diagnostic kit.

Storing the materials as a single glassy preparation provides them in a convenient form for eventual use. For

15 instance, if an assay requires a combination of one or more substrates, and/or a cofactor and an enzyme, two or all three could be stored in a glass in the required concentration ratio and be ready for use in the assay.

If multiple materials are stored, they may be mixed

20 together in an aqueous solution and then incorporated together into a glass. Alternatively they may be incorporated individually into separate glasses which are then mixed together.

When multiple materials are stored as a single

25 composition (which may be two glasses mixed together) one or more of the materials may be a protein, peptide, nucleoside, nucleotide or enzyme cofactor. It is also possible that the materials may be simpler species. For instance a standard

assay procedure may require pyruvate and NADH to be present together. Both can be stored alone with acceptable stability. However, when brought together in aqueous solution they begin to react. If put together in required

5   proportions in the glassy state they do not react and the glass can be stored.

Material to be Stored (ii) cells

In a significant development of this invention we have

10   found that the material which is stored may comprise viable biological cells. The composition obtained by spray drying can then contain the cells in a state of suspended animation, and viable cells can be recovered from storage. Cells which may be placed in a storable condition by the

15   method of the invention will preferably be existing as single cells, being either a single cell organism or being cells which are in culture as individual, undifferentiated cells. In particular the cells may be a bacterial culture, which may be isolated from nature or may be a laboratory or

20   industrial bacterial strain including genetically transformed bacteria. The cells may be eukaryotic cells, notably including yeasts but also other fungal cultures. Again the cell culture may be a natural isolate or a laboratory or industrial culture produced by fermentation

25   including genetically transformed strains.

The Carrier Substance

A glass is defined as an undercooled liquid with a

very high viscosity, that is to say at least 10^{13} Pa.s, probably 10^{14} Pa.s or more.

Normally a glass presents the appearance of a homogeneous, transparent, brittle solid which can be ground or milled to a powder. In a glass, diffusive processes take place at extremely low rates, such as microns per year. Chemical or biochemical changes involving more than one reacting moiety are practically inhibited.

Above a temperature known as the glass transition temperature T_g, the viscosity drops rapidly and the glass turns into a rubber, then into a deformable plastic which at even higher temperatures turns into a fluid.

The carrier substance employed in this invention must be hydrophilic - either water-soluble or water-swellable - so that water will act as a plasticiser. Many hydrophilic materials, both of a monomeric and a polymeric nature either exist in an amorphous state or can be converted into such an amorphous state which exhibit the glass/rubber transitions characteristic of amorphous macromolecules. They have well defined glass transition temperatures T_g which depend on the molecular weight and on molecular complexity of the substance concerned. T_g is depressed by the addition of diluents. Water is the universal plasticiser for all such hydrophilic materials. Therefore, the glass/rubber transition temperature is adjustable by the addition of water or an aqueous solution.

It will generally be preferred to employ a carrier substance which, on its own, forms a glass rather than a

rubber at ambient temperature. Hence it will be preferable that the carrier substance, on its own, is able to exist in a glassy amorphous state with a glass transition temperature T_g above 20°C.

5   Mixtures of substances may be used as carrier substance if the components are miscible as a solid solution. If so, material(s) of lower T_g serve as plasticiser(s) for material(s) of higher T_g.

A composition prepared by a process of this invention

10   will generally have a glass transition temperature T_g below that of the pure carrier substance.

If the dried composition is stored in the glassy state (below T_g) the deterioration of the active material is retarded to the extent that, on practical time-scales, even

15   substances which in solution are extremely labile are found to possess long shelf-lives.

Full biochemical activity is maintained, but locked in, throughout this period at temperatures below T_g and can be rapidly released by resolubilization of the glass in an

20   aqueous medium.

If the material to be stored is inanimate, then in order to provide a long storage life, it will generally be desirable that the dried composition has a glass transition temperature of at least 20°C. For achieving this it is

25   desirable that the glass-forming carrier substance, when anhydrous or nearly so, displays a glass transition temperature T_g of at least 40°C, better at least 50°C. There is no theoretical upper limit on T_g. In practice

suitable materials have values of T_g below 250°C, usually below 200°C. A desirable range is therefore 50° to 200°C, preferably 60° or 80°C to 150° or 180°C.

If the material to be stored comprises biological cells, the composition containing the cells may well be in an amorphous rubbery state. Thus a composition obtained by the method of the invention and comprising biological cells may have a glass transition temperature T_g below 20°C for instance in the range between 0°C and 20°C even though its carrier substance has a glass transition temperature above 20°C. Such compositions could readily be stored with refrigeration to approximately 0°C so as to be stored in the glassy rather than rubbery state.

If T_g of the final composition made according to the invention is sufficiently high, storage can be at room temperature. However, if T_g of the composition is close to or below room temperature it may be necessary or desirable to refrigerate the composition if storage is for a prolonged period. This is less convenient but still is more economical than freeze-drying.

If a composition is heated above its T_g during storage, it will change to its rubbery state. Even in this condition stored materials are stable for a considerable period of time. Consequently, it may well do no harm if the temperature of a stored composition is allowed to rise above T_g for a limited time, such as during transportation.

If a composition is maintained slightly above its T_g (and therefore in a rubbery condition) the storage life will

be limited but still considerable and the benefit of the invention will be obtained to a reduced extent.

Conversely, if T_g of the composition is well above room temperature, the composition is better able to withstand

5 storage at an elevated temperature, e.g. in a hot climate.

The carrier substance should be sufficiently chemically inert towards an inanimate material which is to be incorporated in it. An absolute absence of chemical reactivity may not be essential, as long as it is possible

10 to incorporate the material, store the glass, and recover the material without serious degradation through chemical reaction.

If the material to be stored comprises biological cells, the carrier substance should not be toxic to these

15 cells. Indeed the carrier substance may be a nutrient for the cells and able to support cell division so long as the drying operation is carried out at sufficient rapidity that the carrier substance is not consumed by the cells.

As mentioned above, the carrier substance, which very

20 preferably forms a glass, may be deliberately added to form the mixture which is spray dried. For instance it may be added to a solution of the material to be stored.

Many organic substances and mixtures of substances will form a glassy state on cooling from a melt.

25 In this context carbohydrates are an important group of glass forming substances: thus candy is a glassy form of sugar (glucose or sucrose). The T_g for glucose, maltose and maltotriose are respectively 31, 43 and 76°C. (L. Slade and

H. Levine, Non-equilibrium behaviour of small carbohydrate-water systems, Pure Appl. Chem. $\underline{60}$ 1841 (1988)). Water depresses T_g and for these carbohydrates the depression of T_g by small amounts of moisture is approximately 6°C for

5   each percent of moisture added. We have determined the T_g value for sucrose as 65°C.

In addition to straightforward carbohydrates, other polyhydroxy compounds can be used, such as carbohydrate derivatives and chemically modified carbohydrates (i.e.

10   carbohydrates which have undergone chemical reaction to alter substituents on the carbon backbone of the molecule but without alteration of that backbone).

Another important class of glass forming substances are water-soluble or water-swellable synthetic polymers, such as

15   polyacrylamide.

Yet another class of substances which are suitable are proteins and protein hydrolysates. Thus albumin can be used, and so can hydrolysis products of gelatin.

A group of glass forming substances which may in

20   particular be employed are sugar copolymers described in US Patent 3 300 474 and sold by Pharmacia under the Registered Trade Mark "Ficoll". This US patent describes the materials as having molecular weight 5,000 to 1,000,000 and containing sucrose residues linked through ether bridges to

25   bifunctional groups. Such groups may be alkylene of 2, 3 or more carbon atoms but not normally more than 10 carbon atoms. The bifunctional groups serve to connect sugar residues together. These polymers may for example be made

by reaction of the sugar with a halohydrin or a bis-epoxy compound.

The suitability of an intended carrier substance, and the amount of material which can be incorporated into it

5 can both be checked by preparing a glassy or rubbery composition with the material incorporated, and then recovering the material without any substantial period of storage.

T_g values can be determined with a differential

10 scanning calorimeter and can be detected as a point at which a plot of heat input against temperature passes through an inflection point - giving a maximum of the first temperature derivative.

As was also mentioned above, a further possibility is

15 that the material which is to be stored may occur in a form which incorporates a suitable carrier substance. It is envisaged in particular that this situation may arise with products derived from blood plasma where the material to be stored is a relatively minor component of the blood plasma

20 and other components which naturally occur in the blood plasma, notably albumin, are able to form a glass on drying. In such a situation there would be no need for separate addition of a glass-forming carrier substance although the possibility is not ruled out.

25

Processing

The first stage is to provide an aqueous mixture of the material to be stored and the water-soluble or water-

swellable carrier substance. This may be done by mixing the carrier substance, as a powder or as an aqueous solution, with a solution or suspension of the active material to be stored. Alternatively a suitable solution may be available

5   from some other process, without requiring deliberate addition of glass-forming carrier, as mentioned above.

When the invention is applied to the storage of cells, a possibility which has been found suitable for some cells is to suspend the cells in a dilute aqueous solution

10   containing the carrier substance and then subject this to the drying step. To arrive at the suspension, solid carrier material may be dissolved in a suspension of the cells in a dilute aqueous buffer solution. This can lead to a composition with a glass transition temperature above

15   ambient and temperature having very good storage stability.

For some cells, it has been found that survival during drying is better if the cells are dried from a mixture which is rather closer to their normal growth medium. This may for example be carried out by adding carrier substance to an

20   aqueous culture of the cells in their growth medium and drying the resulting mixture. Many bacteriological growth media have a relatively high electrolyte content and this electrolyte or other components is effective to lower the glass transition temperature of the dried product. If this

25   procedure is followed the composition is likely to have a glass transition temperature below ambient temperature making it desirable to store the composition under refrigeration. In this situation the need for refrigerated

storage is accepted for the sake of greater survival of cells during the drying operation.

In order to determine whether any cell species can be dried from a simple aqueous suspension or whether it should be dried from something akin to its growth medium, a test can be made by drying some cells by each procedure, then recovering the cells without storing for any substantial period of time and determining the quantity of cells which have survived.

After arriving at a mixture containing the material to be stored and a carrier substance the next step is a spray drying operation in which the above aqueous mixture is sprayed into a hot gas stream. The gas will generally be air but could be some other gas such as nitrogen.

Apparatus to carry out spray drying on a fairly small scale is available from various manufacturers. One is Drytec Ltd, Tonbridge, Kent who manufacture a pilot plant scale dryer. Another manufacturer is Lab-Plant Ltd of Longwood, Huddersfield, England who manufacture a laboratory scale dryer.

Process plant to carry out spray drying on a larger scale is also well known.

The sole drawing is a diagrammatic illustration of laboratory scale spray-drying apparatus.

In this apparatus air from the atmosphere is drawn in by a blower 10 and passes over an electric heater 12 after which the air passes down a main chamber 16. The aqueous mixture to be sprayed is drawn up from a supply vessel 18

means of a peristaltic metering pump 20 and delivered to a
spray nozzle 22 which discharges the aqueous mixture as a
fine spray into the stream of hot air coming from the heater
12.

5   The droplets of spray are dried to solid powder form as
they pass down within the main chamber 16. The powder is
entrained in the air which has passed down the main chamber
16. This leaves by an exit tube 26 at one side delivering
to a cyclone separator 28 which serves to remove entrained

10 solid particles from the air stream. The solid particles
which are separated from the air stream in this way are
collected as the product in a detachable vessel 30 while the
air passes out to atmosphere through an exhaust tube 32.
Solids which stick to the wall of the main chamber fall into

15 waste container 24.

    A significant parameter in the operation of any spray
drying apparatus is the temperature of the gas stream which
is admitted to the main chamber and into which the spray is
delivered. For the present invention this inlet temperature

20 of the gas stream will generally exceed 80°C, will usually
exceed 90°C and may well lie in a range from 100 to
250/300°C.

    The aqueous mixture which is delivered into the gas
stream may typically contain from 10 up to 50 or even 250

25 grams per litre of the carrier substance. The content of
material to be stored can vary widely but will often lie
within a broad range from 10^{-3}% to 10% by weight of the
carrier substance. Much lower levels are possible. A

substance whose desired activity is present when very dilute might be stored at a concentration as low as 10^{-5}% by weight of the dried composition. By contrast storage at a concentration of stored material of up to 50% by weight or

5 even more can also be envisaged.

In many instances the carrier substance will form at least 20%, better at least 25% or 30% by weight of the particulate composition formed by drying and usually at least 50% by weight of that particulate composition.

10 The particulate solid compositions produced by discharging an aqueous mixture into a heated gas stream in accordance with the invention will frequently be sufficiently dry for storage without further processing. However it is within the scope of the invention to subject

15 these compositions to further drying such as by subjecting them to sub-atmospheric pressure possibly accompanied by moderate heating so as to reduce any residual moisture content.

When the material to be stored comprises biological

20 cells the moisture content of a composition produced by a method of the invention would typically be in the range 3 to 9% by weight. A low moisture content enhances stability.

The suitability of conditions for preparing a storable composition can be checked by carrying out the preparation

25 but recovering the material without any substantial period of storage and determining the proportion which has survived. As mentioned above storage stability can if desired be tested by storage at a temperature above ambient,

although not above the T_g value of the glass.

Recovery from storage

Recovery of stored material from a composition produced

5   by drying in accordance with this invention can be effected
by simply adding water or aqueous solution to a quantity of
the composition with the active material therein. If the
carrier substance is water-soluble the result is a solution
of the material and the carrier substance.

10   Separation by chromatography to isolate a stored,
active, inanimate material from the carrier substance is
possible. However, in general it will be neither desirable
nor necessary. Instead the carrier substance is chosen so
that it will not interfere with the use (e.g. an assay) of

15   the stored, active material.

In the case of a water-swellable carrier
substance, it will remain out of solution, perhaps as a gel,
and the solution of the material can be separated by
centrifugation if required.

20   A further aspect of this invention is use of a
composition prepared according to the invention to provide a
solution of the stored material, by addition of water or
aqueous solution to the composition. The application to
which the solution of recovered material is put may or may

25   not be a therapeutic application.

Example 1

The active material to be placed in a storable form was

lactate dehydrogenase (LDH) type XI (ex rabbit muscle) from Sigma Chemical Co. The glass forming carrier substance employed was Ficoll 400 DL (Pharmacia, Reg. Trade Mark) which is a copolymer of sucrose and epichlorohydrin. It is

5 water-soluble and has a T_g of 97°C.

8 g of Ficoll was added to 200 ml of 0.01 M phosphate buffer pH 7 and stirred at ambient temperature until a clear solution was obtained. This solution was then cooled to, and stored at, 4°C until use. All solutions were used

10 within 72 hr. To 200 ml of the phosphate buffer/Ficoll solution (at 4°C) 10 mg of LDH was added. The resulting solution was then passed through a spray-drier (Drytec, pilot scale drier) to give a dry powder containing 1.25 mg LDH/g powder. An air inlet temperature of 210°C (at the air

15 inlet to the drying chamber) was employed; this produced an air temperature of 70°C at the entry to the cyclone separator.

The dried material was a particulate solid. This was divided into 2 g portions and placed into vials. The vials

20 were sealed under a normal atmosphere and stored at ambient temperature (fluctuating between 10 and 35°C). Portions of powder were periodically removed and the vials resealed. Assays were performed following drying, and periodically thereafter. An assay of the solution prior to drying was

25 used as the control.

The actual enzyme activity was determined by the following procedure (Hatley, Franks and Mathias, Process Biochemistry, December 1987 page 170) and based on a minimum

of nine replicates. The powder was dissolved in phosphate buffer to give a test solution calculated to contain 1 µg protein per ml (for the control sample a portion of the solution to be dried was taken and diluted to 1 µg per ml).

Activity of the test solution was then measured: 2.7 ml of 0.01 phosphate buffer pH 7, 0.1 ml of 2mg/ml NADH and 0.1 ml of 10 mM pyruvate were placed into a cuvette of light path 10 mm. The cuvette was capped and shaken. 0.1 ml of the test solution was added and the cuvette again capped and shaken. The absorbance at 340 nm was recorded at 30 s intervals for a total of three minutes. The temperature of the solution was also noted. The absorbance change per minute, δA, was calculated. The enzyme activity was then calculated as follows:

$$\text{LDH activity (units/mg)} = \frac{\delta A \times TCF}{6.25 \times C}$$

where:

δA = the absorbance change per minute

6.25 = a correction factor for the molar absorbance of NADH.

TCF = a temperature correction factor applied to all assays performed at temperatures other than 25°C

C = the concentration of protein in mg/ml

The control (unprocessed) solution had an activity of 322 U/mg protein. This was taken as 100% and all subsequent assays quoted relative to this value. Enzyme activities were:

	Before Drying	Storage period after drying (days)				
		0	12	33	91	138
5	100%	82%	83%	86%	71%	100%

Product T_g was determined throughout the storage period. The value decreased from 79°C to 64°C as moisture entered the product as it was repeatedly opened and

10 resealed. However, throughout the experiment the product remained in the form of a glass at the storage temperature.

The results show that enzyme activity was effectively preserved intact through the spray drying procedure and subsequent storage.

15

Example 2

Example 1 was repeated with an air inlet temperature of 130°C. This produced an air temperature of 60°C at the entry to the cyclone separator. After 138 days storage,

20 enzyme activity was 112% of the control value.

Example 3

Example 1 was repeated with two variations. 50 mg of LDH was added to 200 ml of the phosphate buffer/Ficoll

25 solution (at 4°C). Spray drying gave a dry powder containing 6.25 mg LDH/g powder. Air inlet temperature was 150°C. This produced an air temperature of 70°C at the entry to the cyclone separator.

After 138 days storage enzyme activity was 117% of the

control value.

Example 4

The active material was alcohol oxidase from Provesta
Enzymes. The glass forming substance employed was Ficoll
400 DL (Pharmacia, Reg. Trade Mark) as used in Example 1.

8 g of Ficoll was added to 200 ml of 0.1 M phosphate
buffer pH 7.5 and stirred at ambient temperature until a
clear solution was obtained. This solution was then cooled
to, and stored at, 4°C until use. All solutions were used
within 72 hr. 100 µg (100 units) of alcohol oxidase was
added to 200 ml of the phosphate buffer/Ficoll solution (at
4°C). The resulting solution was then passed through a
spray-drier (Drytec pilot scale drier) to give a dry powder
calculated to contain 0.0125 U alcohol oxidase/g powder. An
air inlet temperature of 150°C was employed; this produced
an air temperature of 70°C at the entry to the cyclone
separator.

The dried material was divided into 2 g portions and
placed into vials. The vials were sealed under a normal
atmosphere and stored at ambient temperature (fluctuating
between 10 and 35°C). Portions of powder were periodically
removed and the vials resealed. Assays were performed prior
to drying and following drying.

As a comparison freeze-dried samples were prepared
using principles described in the literature, (F Franks.
Cryo-Letters 11, 93-110). 300 mg of Ficoll was dissolved in
20 ml of 0.1 M phosphate buffer pH 7. 1000 units of alcohol

oxidase was added to the solution. The solution was divided into 0.2 ml portions in ten 5 ml vials. These were frozen to -30°C in a small laboratory freeze-drier. A vacuum of 1 x 10^{-1} mbar was applied and the samples dried for 24 hr.

5 The vacuum was reduced to its minimum setting of 5 x 10^{-2} mbar and the temperature raised at 5°C/hr to 30°C. After holding the sample at this temperature for two hours the vials were removed and sealed with Bakelite screw-caps. Each vial was calculated to contain 1 unit of enzyme,

10 assuming no activity had been lost during processing. Enzyme activity was assayed before and after freeze drying.

As a further comparison, samples of solution similar to those which were freeze dried, were dried in stationary vials, as described in our published European application

15 EP-A-383569. Enzyme activity was assayed before and after drying.

Assays of enzyme activity were performed as follows: Dried powder was dissolved in phosphate buffer to give a test solution calculated to be 0.1 U per ml (for the control

20 sample a portion of the solution to be dried was taken and serially diluted to 0.1 U per ml).

A stock solution was prepared containing:

16 mg 2,2'-azino-di(3-ethylbenzthiazoline-6-sulphonic acid)

25 (ABTS)

2 ml absolute ethanol

1 ml of 1 mg/ml horseradish peroxidase in distilled water

All made up to 100 ml with 0.1 M potassium phosphate buffer,

pH 7.5.

Another stock solution was:

0.1 M potassium phosphate buffer, pH 7.5.

5

2.5 ml of the ABTS stock solution was pipetted into a 3 ml cuvette, 25 µl of the enzyme solution with an expected activity of 0.1 U alcohol oxidase per ml was added. The cuvette was closed and its contents mixed by inversion. The

10 cuvette was placed in a spectrophotometer and the absorbance change over 3 min at 390 nm recorded.

The absorbance change per minute was determined and multiplied by 3.06 (the extinction coefficient plus the cuvette dilution factor) to give the concentration of enzyme

15 in the solution. Activity retention was calculated by dividing the measured value by 0.1 (the expected activity in the solution) and multiplying by 100 to give a percentage.

It was found that after drying the activity as a percentage of that before drying was:

20

Freeze drying	35%
Drying in stationary vial	38%
Spray drying	52% compared to produced, still better

25 Suppliers' catalogues show that commercial freeze drying of alcohol oxidase reduces activity to 25%.

The spray dried and freeze dried alcohol oxidase were stored at 35°C and activity was assessed at intervals. The

freeze dried material lost all activity in 20 days. After 30 days the spray dried material retained 90% of its activity assayed directly after spray drying.

5   Example 5

Example 1 was repeated, replacing Ficoll with Byco A which is a cold water soluble protein obtained from gelatin by enzymic hydrolysis. It has a T_g value of 126°C. Byco A is available from Croda Colloids Ltd, Widnes, Cheshire,

10   England.

As in Example 1 enzyme activity was measured both directly following drying and after a period of storage. The measured values of enzyme activity were 88% directly following drying and 113% after 103 days storage at ambient

15   temperature.

Example 6

As in Example 1, the active material was lactate dehydrogenase (LDH) type XI and the glass forming substance was Ficoll 400 DL.

10 g of Ficoll was added to 100 ml of 0.01 M phosphate buffer pH 7 and stirred at ambient temperature until a clear solution was obtained. This solution was then cooled to, and stored at, 4°C until use. All solutions were used within 72 hr. 10 mg of LDH was added to 200 ml of the phosphate buffer/Ficoll solution (at 4°C). The solution was then passed through a spray-drier (Lab-Plant SD-04) to give a dry powder containing 1 mg LDH/g powder. An air inlet temperature of 170°C was employed; this produced an air outlet temperature of 75°C. The dried material was sealed in a collection bottle in a normal atmosphere. The samples were stored at ambient temperature (fluctuating between 10 and 35°C). Portions of powder were periodically removed and assays performed as for Example 1.

Enzyme activities were:

	Storage period (days)	
Before Drying	0	61
100%	91%	103%

Example 7

This example describes converting biological cells into a
storable composition by a method embodying the invention and
then recovering the cells after varying periods of time.

5   The amount of aqueous solution used in recovery of
cells was chosen such that, if there was survival of every
cell, the concentration of cells in the recovered suspension
would be the same as in the initial suspension before
drying. The concentrations of viable cells in these
10 suspensions, before drying and after recovery, were assayed
by using a standard quantity of the suspension to make an
agar plate. The plate is then incubated and the number of
growing colonies was counted.

15 5 g Ficoll 400 DL (Pharmacia, Reg Trade Mark) was dissolved
in 100 ml growth medium. 5 ml Lactobacillus bulgaricus
cells in growth medium were added to the Ficoll solution to
give a cell suspension of approximately 1 x 107 cells/ml.
The suspension was then spray dried, using a laboratory
20 scale spray drier, (Lab-Plant SD-04), with input
temperature 190°C and output temperature 104°C, and
collected as a dry powder. The powder was immediately
dispensed into several small vials and the vials were capped
and stored at 4°C.
25 Viability testing:

Before drying (control):

0.5 ml cell suspension was transferred to a sterile tube
containing 9.5 ml sterile growth medium. Serial dilutions

were made in the manner of Miles and Misra. 1 ml cell
suspension from an appropriate dilution was transferred to
a 9 cm sterile petri dish and mixed with 10 ml molten
growth medium at approximately 37°C. The agar plate was
5 then allowed to set and incubated for 48 h at 35°C. The
colony forming units were then counted.

After drying:

0.5 ml growth medium was added to 0.049 g dried powder
(calculated weight of solids in 0.5 ml original cell
10 suspension) and left to stand at room temperature for 30
min to ensure full rehydration. The assay was continued as
described above and the number of colony forming units was
compared to the number found in the sample assayed before
drying.

15 Further dried samples were assayed at intervals.

Results:

Storage time	Cfu's in 10^{-5} dilution	% of control
20 Before drying (control)	1365	
Directly after drying	344	25
2 weeks	345	25
25 4 weeks	319	23

Example 8

5 g Dextrin 10 (maltodextrin, ex Fluka) was dissolved in 100 ml 10% skimmed milk solution. 5 ml Lactobacillus bulgaricus cells in growth medium were then added to the

5   solution to give a cell suspension of approximately 1×10^7 cells/ml. The suspension was then spray dried, using a laboratory scale spray drier, (Lab-Plant SD-04), with input temperature 160°C and output temperature 89°C, and collected as a dry powder. The powder was immediately

10   dispensed into several small vials and the vials were capped and stored at 4°C.

Viability testing was carried out as in the previous Example. For testing after drying 0.5ml growth medium was added to 0.076g dried powder as the calculated weight of

15   solids in 0.5ml of the original cell suspension.

Results:

Storage time	Cfu's in 10^{-5} dilution	% of control
Before drying (control)	1321	
Directly after drying	543	41
2 weeks	551	42
4 weeks	392	30

20
25

The moisture content of the spray dried powder was measured by a Karl Fischer coulometric method and found to be 5.2 %.

Example 9

5 g raffinose was dissolved in 100 ml growth medium. 5 ml
Lactobacillus bulgaricus cells in growth medium were added
to the solution to give a cell suspension of approximately

5   1 x 107 cells/ml. The suspension was then spray dried,
using a laboratory scale spray drier, (Lab-Plant SD-04),
with input temperature 190°C and output temperature 108°C,
and collected as a dry powder. The powder was immediately
dispensed into several small vials and the vials were

10   capped and stored at 4°C.

Viability testing was carried out as in Example 7.

Results:

Storage time	Cfu's in 10^{-5} dilution	% of control
Before drying (control)	1620	
Directly after drying	127	8
2 weeks	174	11
4 weeks	176	11
8 weeks	117	7

Example 10

5 g sodium glutamate was dissolved in 100 ml growth medium.
5 ml <u>Lactobacillus bulgaricus</u> cells in growth medium were
added to the solution to give a cell suspension of
approximately 1 x 107 cells/ml. The suspension was then
spray dried, using a laboratory scale spray drier,
(Lab-Plant SD-04), with input temperature 190°C and output
temperature 114°C, and collected as a dry powder. The
powder was immediately dispensed into several small vials
and the vials were capped and stored at 4°C.

<u>Viability testing</u> was carried out as in Example 7.

Results:

Storage time	Cfu's in 10^{-5} dilution	% of control
Before drying (control)	1472	
Directly after	515	35
2 weeks	516	35
4 weeks	534	36
8 weeks	451	31
